To the Editor:

We read with great interest the study by Kang et al\(^1\) that explored the relationship between intravascular ultrasound parameters and fractional flow reserve (FFR) in the assessment of intermediate coronary stenoses.\(^1\) We congratulate the authors, who concluded that lesions with a mean luminal area of $<2.4 \text{ mm}^2$ had a high sensitivity and negative predictive value to predict $\text{FFR} < 0.8$, but this was with a poor specificity and positive predictive value. These findings are not unexpected, given that lesion severity is only one of the features that determine the hemodynamic significance of a lesion. The Hagen-Poiseuille equation states that flow in a tube is determined by $(\Delta P \pi r^4)/(8\eta l)$, where $l$ and $r$ are length and radius of the tube, respectively, and $\eta$ the viscosity and $\Delta P$ the pressure gradient across the tube. Thus there are other factors that may affect coronary blood flow other than intravascular derived severity of a lesion.

Although FFR has been validated in patients studied late after ST-elevation–myocardial infarction,\(^2\) Tamita et al\(^3\) demonstrated that FFR may underestimate the significance of culprit lesions early after ST-elevation–myocardial infarction. Kang et al\(^4\) included patients with non–ST-elevation–myocardial infarction, and there is a paucity of data validating FFR in this population. Microvascular resistance is assumed to be minimal and constant in the simplified FFR calculation. Clinical syndromes that may increase microvascular resistance such as non–ST-elevation–myocardial infarction can affect FFR by altering distal pressure.\(^5\)

The impact of increased lesion length on coronary flow and microvascular resistance on the assessment of FFR require further investigation to better understand the relationship between intravascular ultrasound and FFR parameters.
