Transcatheter Aortic Valve Implantation in Patients With Severe Left Ventricular Dysfunction
Immediate and Mid-Term Results, A Multicenter Study

Background—Few data exist about transcatheter aortic valve implantation (TAVI) in patients with low ejection fraction. The aim of the study was to analyze safety, feasibility, and efficacy of TAVI in patients with severe left ventricular dysfunction.

Methods and Results—The study sample (384 patients) was divided into 2 groups: group A (50 patients) with left ventricular ejection fraction (LVEF) ≤35%, and group B (334 patients) with LVEF >35%. Clinical, anatomic, and hemodynamic variables, as well as procedural results and follow-up outcomes, were compared between the groups. Procedural success was reached in 88%, with no significant difference between the groups. The incidence of periprosthetic leak ≥2+ after TAVI was higher in group A. All other complications were similar between the 2 groups. Group A showed a significant and early improvement in LVEF (from 27.7±6.0–35.2±11.1 after TAVI; P=0.0001). Thirty-day mortality was 4%; however, this was higher in group A compared with group B (10% versus 3%; P=0.010). Predictors of the cumulative late mortality were congestive heart failure, logistic euroSCORE, and moderate-to-severe periprosthetic leakage after TAVI. Estimated survival by Kaplan Meier at 1 year was, respectively, 69% in group A and 87% in group B (log rank <0.0001).

Conclusions—Transcatheter aortic valve implantation is a safe and effective procedure, even in patients with severe left ventricular dysfunction, leading to a high procedural success rate with an acceptable rate of complications and 30-day mortality. Also in these critically ill patients, TAVI provides clinical amelioration, with early improvement in LVEF. (Circ Cardiovasc Interv. 2012;5:253-260.)

Key Words: transcatheter aortic valve implantation ■ aortic stenosis ■ left ventricular dysfunction ■ left ventricular ejection fraction ■ 30-day mortality

Degenerative aortic valve stenosis is the most common valvular disease in industrialized countries; this disease typically is found in elderly patients, and its prevalence will increase with the progressive lengthening in life expectancy.1 The prognosis of symptomatic patients left untreated is poor, with about 75% of patients dying within 3 years of symptom onset.2 Medical therapy is only a palliative measure, as the left ventricular outflow obstruction must be removed mechanically. Although current guidelines recommend surgical valve replacement as the therapy of choice in all symptomatic patients with severe aortic stenosis and in asymptomatic patients, who have already developed left ventricular dysfunction (class I),3 in the real world about one third of patients are excluded or not considered for surgery because of inoperability or high surgical risk due to advanced age or multiple comorbidities.1

This clinical issue stimulated the research and development of alternative less invasive techniques. In 2002, Professor Alain Cribier and his collaborators4 developed a new interventional technique, transcatheter aortic valve implantation (TAVI). This procedure is currently the only therapeutic option in truly inoperable patients5–7 and may represent a viable alternative to traditional surgical aortic valve replacement in high surgical risk patients,8–12 as was recently presented in the results of Cohort A of the Partner trial.13 Among patients at increased operative risk, who are therefore often excluded from surgical intervention, there are those with severe left ventricular dysfunction.14 In these
patients, the transvalvular aortic gradient often is reduced due to low cardiac output, and sometimes a differential diagnosis of “pseudostenosis” can be challenging.15,16

Transcatheter aortic valve implantation now has demonstrated excellent immediate and long-term results.17–20 However, less is known about the safety and efficacy of this technique in patients with left ventricular dysfunction.21,22

The aim of this study is to assess the immediate procedural results and long-term outcomes after TAVI in patients with severe aortic stenosis and severe left ventricular dysfunction, and to compare these with those of patients with normal or only moderately depressed left ventricular function to obtain information on the safety, feasibility, and efficacy of TAVI in this particular clinical context.

WHAT IS KNOWN

- Transcatheter aortic valve implantation (TAVI) has demonstrated excellent results in inoperable and high risk patients affected by severe aortic stenosis.
- Impairment in left ventricular function increases the surgical risk for conventional aortic valve replacement.

WHAT THE STUDY ADDS

- The presence of severe left ventricular dysfunction is not infrequent, being 13% of our TAVI treated population.
- Despite the fact that patients with left ventricular dysfunction were sicker and had more comorbidities, TAVI seems to be a safe and effective procedure providing a prompt and sustained improvement in clinical and left ventricular ejection function.
- The presence of severe left ventricular dysfunction is not to be considered a contraindication to TAVI.

Methods

Study Sample and Study Design

This is a retrospective analysis of prospectively collected data within a dedicated database that includes all patients with symptomatic aortic valve stenosis (aortic valve area ≤0.6 cm²/m²), who underwent TAVI between June 2007 and December 2010, in 2 Italian hospitals, the Cardiology Clinic of the University of Padua and the Laboratory of Hemodynamics of the Scientific Institute San Raffaele in Milan. All patients were deemed inoperable or at high surgical risk for conventional surgery by a multidisciplinary team consisting of cardiology, anesthesiology, and cardioangiography.

Follow-Up Clinical and echocardiographic follow-up was recorded. In particular, data regarding death, cardiovascular death, and functional status (according to New York Heart Association [NYHA] classification) were collected. Prosthesis function (peak and mean transvalvular gradient, peri-, or intraprosthetic leakage), as well as LVEF, also was evaluated using transthoracic echocardiography.

Statistical Analysis

Categorical data are expressed as numbers and percentages and compared by Fisher exact or χ² test as appropriate; in particular we used Fisher exact test when the expected frequencies were less than 5 in more than 20% of cells table; continuous variables are expressed as mean±standard deviation and compared using Student t test (including comparison between LVEF changes from admission to discharge). Linear mixed effects model with an unstructured covariance matrix was used to evaluate LVEF from baseline to follow-up: we tested for the group, the time, and the group by time interaction effect. Individual-variable analysis for in hospital mortality was performed using logistic regression analysis. Odds ratios and their corresponding 95% CIs are provided. A Cox proportional hazards regression model was used for cumulative late mortality. Hazards ratios (HRs) and their corresponding 95% CIs are provided. Considering the relatively low number of events rate, in both analyses we limited the number of variables to the most clinically relevant among the statistically significant covariates. Cumulative survival curves for total survival were drawn using the Kaplan Meier method, and the log-rank test was used to compare differences between groups. A 2-tailed probability value of <0.05 was considered statistically significant. Statistical analysis was carried out using the statistical software SPSS version 17.0 for Windows (SPSS, Inc.).

Results

Baseline Characteristics
Mean age of total sample was 80 ± 7 years, and the majority were females (52%). Patients in group A included younger patients with a lower body mass index. Moreover, group A patients were more likely to be symptomatic with dyspnoea and presented with a higher prevalence of diabetes mellitus, previous myocardial infarction, end stage chronic kidney disease requiring hemodialysis, previous permanent pacemaker, and multivessels coronary artery disease. Procedural risk estimated using the logistic euroSCORE, standard euroSCORE, and Society of Thoracic Surgeons score, was significantly higher in group A. Baseline clinical characteristics are shown in Table 1.

Baseline Echocardiographic Data
Mean LVEF measured 52.8 ± 12.8% (27.7 ± 6.0 in group A versus 56.5 ± 8.7 in group B; P<0.0001). Six percent of the sample presented with associated mitral regurgitation >2+/4, according to Sellers classification. The 2 groups differed significantly from each other in terms of peak and mean transvalvular aortic gradient, which were significantly lower in group A, and pulmonary artery systolic pressure, which was higher in group A. Finally, the mean aortic valve annulus diameter was significantly larger in group A. Baseline echocardiographic data are shown in Table 2.

Procedural Technical Details
The majority of patients (75%) were treated using the transfemoral approach, 17% via the transapical approach, and 7% via the trans-subclavian approach, and only 2 patients required usage of the transaortic approach, with no statistically significant difference between groups A and B. The use of self-expandable and balloon expandable prostheses was well balanced in the general sample (47% and 53%, respectively) and between the groups. General anesthesia was necessary in less than one third of cases (32%), with no statistically significant difference between group A and group B; (P=0.39). On the other side, the need of postdilatation was lower in group A than group B (84% versus 94%; P=0.39).

Intra- and Periprocedural Outcome
Procedural success was reached in 88% of the total sample, with no significant difference between the 2 groups. Device success rates were not different between the 2 groups, although there was a trend toward higher device success rates in group B (82% in group A versus 91% in group B, P=0.060). The incidence of periprosthetic leak >2+/4 following the procedure was higher in group A (10% in group A...
versus 3% in group B, \( P = 0.027 \). The incidence of other complications, such as coronary flow obstruction (<1%), device embolization (3%), conversion to cardiac surgery (2%), need for a second prosthesis (4%), cardiac tamponade (2%), and aortic dissection (<1%) was quite low and similar between the groups. The incidence of vascular complications was more frequent, affecting 22% of the sample, but only around half of them were major complications (10% in group A versus 13% in group B, \( P = 0.60 \)). Table 3 shows the details of procedural outcomes.

Mean length of hospital stay was 11±11 days, with no significant difference between the 2 groups. The 30-day mortality and overall hospital mortality rate were 4% and 6%, respectively, with a high proportion of the patients who died being within group A. The incidence of stroke, acute myocardial infarction, sepsis, and acute renal failure requiring ultrafiltration was quite low (<1%, 2%, 4%, and 5%, respectively), and similar between the groups. The rate of permanent pacemakers implanted before discharge was 18% in the whole sample (32% of patients who received a CoreValve versus 6% of patients in which an Edwards Sapien or Sapien XT was implanted, \( P < 0.0001 \)). In hospital events are listed in Table 4.

AV indicates aortic valve.

Change in Left Ventricular Ejection Fraction Over Time

Left ventricular ejection fraction increased significantly in both groups (linear mixed model time effect, \( P < 0.0001 \)), and the magnitude of change was significant between groups (linear mixed model group effect, \( P < 0.0001 \)), and linear mixed model group by time effect, \( P < 0.0001 \); Figure 1, panel A). Patients with severe left ventricular dysfunction at baseline (group A) showed a significant improvement in LVEF at 48 hours echocardiogram. Specifically, the LVEF improved from a mean value of 27.7±6.0% to 35.4±11.0% after implantation of the valve (\( P < 0.0001 \)). In contrast, the patients who had a better LVEF at baseline (group B) did not show any significant improvement at the time of their first postoperative echocardiogram (their ejection fraction changed from 56.5±8.7% to 55.9±9.2%, \( P = 0.24 \)). Although group B had a persistently higher LVEF than group A at each time point during follow-up, the absolute difference between the groups was reduced at 1 year follow-up, due to a trend to progressive improvement in LVEF over time among the patients of the group A. Restricting the analysis only to those patients who had LVEF measured at 1 year (116 patients), we still observed that LVEF increased significantly in both groups (linear mixed model time effect, \( P < 0.0001 \)), and the magnitude of change was significant between groups (linear mixed model group effect, \( P < 0.0001 \), and linear mixed model group by time effect, \( P = 0.001 \)).

Moreover, out of 50 patients in group A, 22 (44%, group A1) had low-flow, low-gradient aortic stenosis (mean gradient <40 mm Hg), and 28 (56%, Group A2) had a mean gradient ≥40 mm Hg. LVEF increased significantly in both subgroups (linear mixed model time effect, \( P < 0.0001 \)), but the magnitude of change was not significant between subgroups (linear mixed model group effect \( P = 0.004 \), and linear mixed model group by time effect, \( P = 0.089 \); Figure 1, panel B). However, although not statistically significant, patients with low-flow, low-gradient aortic stenosis showed almost a 2-fold increase in the in hospital mortality rate compared with patients without low gradient aortic stenosis (18% versus 11%). Finally, in our analysis, permanent pacemaker implantation after TAVI and completeness of coronary revascularization before TAVI had no significant effect on the change in LVEF before and after TAVI.

Follow-Up

Mean follow-up length was 9±8 months (limits 1–36 months), with no significant difference between the 2 groups (8±7 months in group A; 9±8 months in group B, \( P = 0.40 \)). At 30 days a significant improvement in NYHA functional class was already evident, with 94% of patients in NYHA I/II at 30-day follow up (\( P < 0.0001 \) versus baseline value).
At 1-year follow-up (for the 278 eligible patients), all cause death was 14% (40 patients; 29% in group A versus 12% in group B, \( P \leq 0.012 \)). Cardiovascular death was similar between the 2 groups (10% in group A versus 6% in group B; \( P = 0.434 \)). Estimated total survival by Kaplan Meier at 1- and 2-year follow-up was 84% and 73%, respectively, in total sample, 69% and 52% in group A and 87% and 76% in group B (log rank=0.012; Figure 2, panels A and B).

**Predictors of Mortality**

The major independent predictors of the cumulative late mortality were congestive heart failure (\( P < 0.0001 \); HR 2.69; 95% CI, 1.64–4.40), logistic euroSCORE (\( P = 0.002 \); HR 1.02; 95% CI, 1.01–1.04), and moderate-to-severe periprosthetic leakage after TAVI (\( P = 0.043 \); HR 2.19; 95% CI, 1.02–4.67).

**Discussion**

The most important findings of this study are (1) in a subgroup of patients with severe impairment in left ventricular function, procedural success rates are high and statistically similar to that of patients with normal or only a moderate reduction in LVEF, and (2) the intra- and periprocedural complications recorded between the 2 groups of patients were similar.

The device success rate of 90% reported in our total sample might appear lower than other published series, such as the Italian registry (98%),25 the French registry (92.6%),18 the Belgian registry (97%),26 the German registry (98.4%),17 the European SOURCE registry (93.8%),19 and the Canadian experience (93.3%).20 However, this apparent difference probably is due, at least in part, to differential definitions of procedural success between these published results;27 in our study, we followed the recommendations proposed by the VARC Committee.24 Despite similar procedural success rates between the 2 groups of our study, the device success rate tended to be significantly lower in group A because of a higher incidence of significant residual periprosthetic leak postprocedure. This phenomenon may be explained by the presence of larger mean annulus size and less frequent use of balloon predilation in group A; the combination of these 2 factors may have caused inadequate expansion and sealing of the prosthesis to the native aortic valve apparatus in this group. In our series, the strategy of no balloon aortic
between 8% and 21%,29–33 and it depends on the presence of minimal regurgitation, impact significantly on the clinical outcome of these patients at late follow-up.

It is also important to note that a significant early and sustained improvement in LVEF was recorded in group A, with a trend toward a reduction in the absolute difference between the 2 groups at 1-year follow-up. Few studies in the literature have documented improvements in LVEF after TAVI, and even fewer have focused on outcomes in patients with severe left ventricular dysfunction at baseline.22,34–37 The improvement in LVEF obtained after TAVI seems even better than that observed after surgical aortic valve replacement; this may be due, at least in part, to a superior hemodynamic performance of transcatheter prosthesis in terms of the effective orifice area, transprosthetic gradients, and reduction of pressure overload on the left ventricle.35 In addition, we must consider that TAVI, with the exception of the transapical approach, allows for better protection and ensures an improved recovery of myocardial function, while avoiding (or at least minimizing) ischemic and ischemia/reperfusion injury, inflammatory response, cardioplegia, surgical trauma, and oxidative stress, which can lead to apoptosis and contractile dysfunction of survivor myocytes.38

With regards to the follow-up data in our series, the estimated overall survival rate at 1 year for the total sample was 84%, which included both inoperable and high surgical risk patients. In the cohort A of PARTNER trial (high risk patients), this Figure was 75.8%, while in cohort B (inoperable patients) it was 69.3%, significantly better than those patients who were left untreated (49.3%). In our study, the estimated overall survival rate at follow-up was significantly lower in group A than in group B, with an early divergence between the 2 curves.

**Conclusion**

In conclusion, TAVI is a safe and effective procedure, even in patients with severe left ventricular dysfunction, as it leads to procedural success rates that are similar to those of patients with normal or only moderately reduced LVEF, and also leads to clinical improvement in these patients and, in particular, rapid partial recovery of their left ventricular function. Although these results are encouraging, randomized trials data are needed to determine whether this therapeutic approach is able also to improve long-term survival rates in this subgroup of patients.

**Study Limitations**

This study has all the limitations inherent to a relatively small, nonrandomized, retrospective analysis. To this regard, the sample size for low LVEF is unpowered for comparisons of binary data between groups A and B, especially related to the procedural success and adverse events. Another important aspect is the absence of a systematic evaluation of myocardial viability and contractile reserve by low-dose dobutamine predilation was left at the discretion of the operators and performed in a few patients for implantation of both types of prosthesis. Clear evidence supporting the need of balloon predilation before TAVI is lacking, and direct valve implantation seems to give similar acute safety and efficacy results as the standard approach of TAVI with predilation. Moreover, it may offer the advantage of avoiding multiple ventricular pacing that may harm the patients with severe left ventricular dysfunction.28

Additionally, patients with severe impairment in LVEF experienced a higher postprocedural mortality. Thirty-day mortality, which is 4% in the total sample, reached 10% in the subgroup of patients with severe left ventricular dysfunction, around 4 times higher than in group B. However, it is important to note that group A patients had some clinical and demographic characteristics that made them frailer than those in group B. In fact, patients in group A had higher logistic euroSCORE, a lower body mass index, and were more likely to have diabetes, end stage chronic kidney disease requiring hemodialysis, previous myocardial infarction, multivessel coronary artery disease at coronary angiography, and severe symptoms. However, the 30-day mortality in group A (10%) was still far lower than predicted by logistic euroSCORE (39.6% ± 19.4), and was lower than the expected risk after surgical aortic valve replacement. The reported rate of 30-day mortality after surgical aortic valve replacement in patients with severe impairment in LVEF ranges in the literature between 8% and 21%,29–33 and it depends on the presence of contractile reserve. In our study, sample contractile reserve was not evaluated systematically, and there are insufficient data to draw any conclusion. The lack of systematic dobutamine testing prevents us from making a statement regarding potential benefits of TAVI in all patients with LVEF and low gradient. Considering the 19% hospital mortality we reported in these patients, we feel the need to acquire more data to select a subgroup where a risk-benefit ration is achieved. However, low LVEF alone should not be considered a contraindication to TAVI. On the other hand, other procedural characteristics, such as the euroSCORE, history of congestive heart failure, and the presence of relevant mitral regurgitation, impact significantly on the clinical outcome of these patients at late follow-up.
